

Our idea is an interactive Space-Time Travel Planner designed to simulate what a journey to another planet would look like for an individual traveler. First, the program gathers personal data from the user by asking for their current Earth weight and age. Next, it presents a digital menu featuring three planetary destinations: Mars, Jupiter, and Venus. Once the user inputs their choice, the script uses conditional logic to fetch specific predefined scientific statistics for that planet, including its unique gravitational pull and the total travel days required to fly there. With this information loaded, the script performs three core sets of automated calculations where it multiplies the user's Earth weight by the destination's gravity multiplier to show how heavy or light they would feel on that planet's surface. It divides the travel days by 365 to convert the transit duration into Earth years, then adds that value to the traveler's current age. It captures the exact current calendar date from the host computer and uses time-delta mathematics to add the travel days, identifying the precise future date the spacecraft would touch down. Finally, the program generates a clean readout on the screen divided into two organized sections: a "Trip Summary" highlighting the logistical timeline, and "Planetary Metrics" displaying the user's updated physical attributes upon arrival.
